#### Abstract

The generalized independent set problem (GIS) is a generalization of the classical maximum independent set problem and has various practical applications, such as forest harvesting and image/video processing. In this work, we present highly effective exact and heuristic algorithms for the GIS. In the proposed exact algorithm, a new upper bound on the maximum net benefit of an independent set in a subgraph is derived using a Lagrangian relaxation of a linear integer programming formulation of the GIS problem. This bound is then employed in a combinatorial branch-and-bound ( $B \& B$ ) algorithm. To solve larger instances, we propose an adaptive local search procedure which jointly considers several neighborhoods and selects a neighborhood to explore in an adaptive manner at each iteration. Our proposed exact and heuristic algorithms are evaluated on a set of 216 GIS benchmark instances and compared with several state-of-the-art algorithms. Computational results indicate that our proposed algorithm competes favorably with the best existing approaches for the GIS. In particular, the exact algorithm is able to attain all known optimal solutions and to solve 26 more instances to optimality for the first time.

Keywords: Heuristic; branch and bound; adaptive local search; the generalized independent set problem.

[^0]
## 1 Introduction

Given an undirected graph $G=\left(V, E, E^{\prime}\right)$ with two disjoint sets of edges $E$ and $E^{\prime}$ (i.e., $E \cap E^{\prime}=\emptyset$ ), each vertex $v \in V$ is associated with a positive revenue $w_{v}$, and each removable edge $u, v \in E^{\prime}$ is associated with a positive $\operatorname{cost} c_{u v}$. The objective of the generalized independent set (GIS) problem is to find an independent set $I \subseteq V$ such that no two vertices in $I$ are connected by an edge in $E$, while maximizing the net benefit of $I$, which is defined as the difference between the revenues of the vertices in $I$ and the costs of the removable edges with both endpoints in $I$. An example of the GIS is given in Fig. 1, where the dashed edges indicate the removable edges $E^{\prime}$ with their costs, and the set of red vertices (with the revenues shown next to the vertices) represents a candidate solution of the instance. The net benefit of the candidate solution is computed as $w_{b}+w_{c}+w_{e}-c_{c e}=3+2+6-2=9$. In Section 3.2, a mathematical model of the GIS derived from Colombi et al. (2017) is presented.

Fig. 1. An illustration of the generalized independent set problem
When $E^{\prime}$ is an empty set and each vertex has a unit weight, the GIS problem degenerates to the NP-hard maximum independent set (MIS) problem which involves finding an independent set of maximum cardinality. Therefore, the GIS problem is at least as difficult as the MIS problem. The GIS is equivalent to the NP-hard maximum weight independent set problem (Wu et al. 2012) when $E^{\prime}$ is an empty set. Moreover, the GIS is closely related to several other combinatorial optimization problems, such as the maximum edge weighted clique problem (Pullan 2008), the minimum weighted vertex cover (Singh \& Gupta 2006), and the knapsack problem with conflicts (Coniglio et al. 2021). In addition to its theoretical significance, the GIS is a useful model for many applications. A typical application concerns the problem of forest management and harvesting (Hochbaum \& Pathria 1997), where a forest is partitioned into a number of cells and one needs to determine which cells to harvest. More specifically, harvesting a cell can result in a revenue brought
by the timber harvested in that cell, while harvesting two adjacent cells can incur a penalty due to the consideration of wildlife habitat protection. Furthermore, two adjacent cells with a combined area exceeding a stipulated threshold are considered incompatible. The objective of the problem is decide which cells to harvest so as to maximize the net profits. The problem can be formulated by constructing a GIS instance where a vertex corresponds to a cell, a permanent (non-removable) edge corresponds to a pair of incompatible cells, and a removable edge associated with a penalty is created for two compatible adjacent cells. Other applications of GIS can be found in facility location (Hochbaum 2004), cartographic label placement (Mauri et al. 2010), and handling geographic uncertainty in spatial information (Wei \& Murray 2012).

While numerous methods are available for the classic MIS problem and its equivalent maximum clique problem (see review of Wu \& Hao (2015)), only a few exact and heuristic approaches have been proposed in the literature for the GIS as reviewed in Section 2. Given the wide application and NP-hard nature of the problem, powerful exact and heuristic algorithms are needed to increase our capability of solving this challenging problem. The contributions of this work can be summarized as follows.

- We develop an effective exact algorithm based on the branch-and-bound $(B \& B)$ framework, which has several novelties. First, to get a tight upper bound on the maximum net benefit of an independent set in the subgraph, we employ a Lagrangian relaxation method inspired by the basic idea of Hosseinian et al. (2020), which explores a linear integer programming formulation of the problem. Second, we devise an adaptive local search to generate a tight initial lower bound on the optimal objective value of this problem, which helps the exact algorithm to prune more effectively during its search. Third, to efficiently prune the search tree, we employ an effective branching rule by presenting the vertices to the algorithm in a descending revenue order. By incorporating the Lagrangian relaxation upper bound, the tight initial lower bound and the descending revenue order branching rule into the $\mathrm{B} \& \mathrm{~B}$ framework, we obtain an effective exact algorithm for the GIS.
- To obtain high-quality approximate solutions for large instances, we devise an adaptive local search procedure. Our proposed local search is characterized by its neighborhood exploring strategy, which jointly explores several neighborhoods induced by different types of moves and adaptively selects the most promising neighborhood capable of generating high quality solutions.
- To verify the effectiveness of our proposed exact and heuristic algorithms, we compare them with the currently best-performing algorithms by carrying out experiments on a set of 216 well-known GIS benchmark instances. Computational results exhibit that our algorithms compete well with the best existing exact and heuristic algorithms. In particular, our exact
algorithm is able to attain all known optimal solutions reported in the literature, and solve 26 more instances to optimality for the first time. Besides, we generate a new set of 47 larger and more challenging instances to further validate the performance of our proposed heuristic approach.

The rest of the paper is organized as follows. Section 2 presents a literature review on exact and heuristic solution approaches for the GIS problem. Section 3 presents in detail the main components of the proposed branch-and-bound algorithm for the GIS problem, whereas Section 4 provides the main components of the proposed heuristic approach. Computational results and comparisons with the currently best-performing algorithms are given in Section 5. Section 6 investigates some key ingredients of the proposed algorithms, followed by concluding remarks directions in Section 7 .

## 2 Literature review

Due to the relevance of the GIS, several attempts have been devoted to solving this problem. Table 1 summarizes the exact and heuristic solution approaches for the GIS discussed in this section.

To find optimal solutions for the GIS, several exact solution approaches have been proposed in literature. For instance, Hochbaum \& Pathria (1997) developed an integer programming formulation for the GIS in the context of solving forest harvesting optimization problems arising in forest management. For special cases of graphs such as bipartite graphs, they also proposed polynomial-time algorithms to find optimal solutions to the GIS. Colombi et al. (2017) provided the first polyhedral analysis of the problem and studied several classes of valid inequalities. By introducing some of the derived valid inequalities into a 0-1 linear programming formulation, they developed a branch-and-cut algorithm to exactly solve the GIS. Along with the proposed
Table 1
Representative exact and heuristic algorithms for the GIS

| Literature | Framework |  |
| :--- | :--- | :--- |
| Exact algorithms |  |  |
| Hochbaum \& Pathria | Integer programming formulation |  |
| Colombi et al. 2017 |  | Branch and cut |
| Hosseinian \& Butenko | Branch and bound |  |
| Heuristic approaches |  |  |
| Kochenberger et al. | 2007 | Tabu search |
| Colombi et al. | 2017 | Tabu search |
| Nogueira et al. | 2021 | Local search |

exact algorithm, they also proposed a large set of 216 randomly generated instances by extending the classic DIMACS instances, which is widely adopted nowadays to test different GIS approaches in the literature. Their proposed branch-and-cut algorithm solved 94 out of the 216 instances to optimality. Hosseinian \& Butenko (2019) proposed an exact algorithm for the GIS by taking advantage of a quadratic formulation of the GIS. An upper bound was obtained by solving a quadratic relaxation of this formulation. By incorporating the upper bound into the branch-and-bound ( $\mathrm{B} \& \mathrm{~B}$ ) framework, an exact method denoted by CB\&B for the GIS was developed. The algorithm was tested on the same set of 216 instances proposed by Colombi et al. (2017), and was able to solve 118 out of the 216 instances to optimality.

Though exact algorithms are valuable for finding the optimal solutions, their computation time becomes prohibitive when the size of the instance is large. For large sized instances, heuristic approaches are indispensable alternatives for obtaining high-quality near-optimal solutions. Several effective heuristic approaches have been proposed in the literature for the GIS. Kochenberger et al. (2007) developed an unconstrained binary quadratic programming formulation for the problem, which has the advantage of requiring only variables associated with the vertices (no variables associated with the removable edges), leading thus to a nonlinear formulation typically much smaller than its linear counterpart in terms of the number of variables. Based on the nonlinear model, they also developed a tabu search approach and shown its effectiveness by computational experiments. Colombi et al. (2017) developed linear programming (LP) based heuristics for the GIS by introducing some of their derived valid inequalities into a $0-1$ linear programming formulation. In addition, inspired by the probabilistic GRASP-tabu search algorithm proposed by Wang et al. (2013), they also proposed a meta-heuristic method exploiting the binary quadratic programming formulation of the problem proposed by Kochenberger et al. (2007). Recently, Nogueira et al. (2021) proposed a highly effective variable neighborhood descent based iterated local search heuristic (ILS-VND) to solve the GIS by extending their previous iterated local search (ILS) heuristic originally proposed for the maximum weight independent set (MWIS) problem. The ILS-VND heuristic jointly relies on two new neighborhoods, which are explored using a variable neighborhood descent procedure. They reported experiments on the set of 216 benchmark instances proposed by Colombi et al. (2017), indicating that the ILS-VND algorithm is very competitive with the best existing heuristics for the problem.

Our review indicates that the CB\&B algorithm proposed by Hosseinian \& Butenko (2019) and the ILS-VND algorithm proposed by Nogueira et al. (2021) showed an overall best performance when exactly and approximately solving the GIS. Thus, these two algorithms are used as the reference approaches for our comparative study.

## 3 The branch-and-bound algorithm for GIS

### 3.1 The basic procedure

Our exact algorithm for the GIS (called LA-B\&B) relies on the standard B\&B framework, which proves to be one of the most successful paradigms for devising exact algorithms for the independent set problem, its equivalent maximum clique problem, and its weighted case (i.e., the maximum weight independent set problem). The success of a B\&B method for these problems mainly depends on the refined techniques used to derive lower and upper bounds on the size (or weight) of the independent set (clique), and the proper pruning strategies.

LA-B\&B implicitly enumerates the independent sets in the graph by excluding from consideration through a pruning strategy any independent set which can never lead to the maximum net benefit. Basically, the enumeration of independent sets in our $B \& B$ method relies on two global vertex sets: the current independent set $I$ to be expended (also called solution) and a set $P$ of candidate vertices to expand the incumbent independent set. By reference to $I$, set $P$, also called candidate list, is a subset of $V \backslash I$ such that any vertex $v \in P$ can be inserted to $I$ to reach a larger independent set $I=I \cup\{v\}$. To maintain the feasibility of $I$, each vertex of $P$ cannot be connected to any vertex in $I$ by any permanent edge in $E$. This property constitutes a key foundation to our $\mathrm{B} \& \mathrm{~B}$ method.

The general scheme of our LA-B\&B algorithm is summarized in Algorithm 1. At the beginning of the search, we use an adaptive local search procedure to find a feasible solution $I_{\max }$ for the GIS (see Section 4), whose net benefit $W_{\max }$ serves as an initial lower bound for the problem. Then our B\&B starts with an empty independent set $I=\emptyset$ and a candidate list $P=V$ (see lines 2 and 4 in Alg. 1), and continues by examining all independent sets in $V$ until an independent set with the maximum net benefit is found. To achieve this, the algorithm calls the function $M a x G I S$ in a recursive manner, and at each recursion of MaxGIS, a vertex $v \in P$ is selected to expand the independent set $I$. On backtracking, $v$ is removed from $P$ and $I$, and a new vertex in $P$ is selected to append to $I$ by calling again $\operatorname{MaxGIS}$ (see lines 24-26 in Alg. 1).

Without considering the pruning strategy (line 18 in Alg. 1), the algorithm will traverse each independent set in the graph in such a way that it first finds the independent set $I_{1}$ with the maximum net benefit containing the first vertex appearing in $P$. Then it finds the independent set $I_{2}$ with the maximum net benefit in $G \backslash\left\{v_{1}\right\}$ that contains the second vertex appearing in $P$ and so on. During the search process, each time an independent set $I$

```

    end function
```

with its net benefit $W$ larger than that of $I_{\max }$ is found, $I_{\max }$ and $W_{\max }$ are updated by $I$ and $W$, which can serve as a tight lower bound employed in the pruning strategy to better prune some branches of the search tree during the subsequent search. The pruning strategy operates as follows: given the current independent set $I$ and its corresponding candidate list $P$, an upper bound on the maximum net benefit of the independent set in $G_{P}$ is calculated using the Lagrangian relaxation method (see Section 3.2), where $G_{P}$ is the subgraph induced by $P$. If this upper bound is not larger than the current lower bound $W_{\max }$ found so far, I cannot lead to an independent set with a net benefit larger than $W_{\max }$, and as a result, the associated node in the search tree can be safely pruned by excluding from further consideration of the corresponding subgraph. Otherwise, the node in the search tree rooted at $I$ and $P$ needs to
be further explored. In this case, a branching rule is applied to determine the next vertex $v$ to be selected from $P$ to append to the current independent $I$ (line 19 in Alg. 1). In our $\mathrm{B} \& \mathrm{~B}$ algorithm, we employ a simple branching rule where the vertices in $P$ are sorted in the decreasing order with respect to their revenue and the vertices in $P$ are selected in that order (Section 3.3). After each branching step, we update $P$ by removing from $P$ all vertices connected to $v$ by a permanent edge in $E$ in order to ensure the required property of $P$.

### 3.2 A Lagrangian relaxation upper-bounding method

Given an undirected graph $G=\left(V, E, E^{\prime}\right)$ with $E$ and $E^{\prime}$ respectively denoting the two disjoint sets of permanent (non-removable) edges and removable edges. For the convenience of presenting the Lagrangian relaxation upper-bounding method, we introduce a removable edge with a cost $c_{i j}=0$ for each pair of vertices $i, j \in V$ which are neither connected by a permanent edge nor by a removable edge (i.e., $\left.\{i, j\} \notin E \cup E^{\prime}\right)$. The optimal solution of the given graph remains unchanged despite the introduction of these removable edges with a cost of 0 . Then the problem can be formulated as the following integer programming model (Colombi et al. 2017):

$$
\begin{align*}
& W^{*}=\max \sum_{i \in V} w_{i} x_{i}-\sum_{\{i, j\} \notin E} c_{i j} y_{i j}  \tag{1}\\
& \text { s.t. } x_{i}+x_{j} \leq 1 \quad\{i, j\} \in E  \tag{2}\\
& x_{i}+x_{j}-y_{i j} \leq 1 \quad\{i, j\} \notin E  \tag{3}\\
& x_{i} \in\{0,1\} \quad i \in V  \tag{4}\\
& y_{i j} \in\{0,1\} \quad\{i, j\} \notin E . \tag{5}
\end{align*}
$$

In the above formulation, each vertex $i \in V$ is associated with a binary variable $x_{i}$ indicating whether vertex $i$ is selected to be a member of the independent set, and each removable edge $\{i, j\} \in E^{\prime}$ (equivalent to $\{i, j\} \notin E$ ) is associated with a binary variable $y_{i j}$ indicating whether a removable edge $\{i, j\} \in E^{\prime}$ is in the independent set. The objective (1) is to maximize the net benefit, defined by the difference between the sum of the revenues of the selected vertices and the costs of those removable edges with both endpoints in the independent set. Constraints (2) ensure that two vertices connected by a permanent edge cannot appear in the independent set together. Constraints (3) ensure that a removable edge $\{i, j\} \in E^{\prime}$ is selected if both of the vertices corresponding to its endpoints are included in the independent set.

Inspired by the work of Hosseinian et al. (2020), we can obtain the following Lagrangian relaxation of the integer programming formulation defined by

Equations (1)-(3), with the exception of the integrality of the variables,

$$
\begin{gather*}
\operatorname{LR}\left(\lambda^{1}, \lambda^{2}\right)=\max _{x, y} \sum_{i \in V} w_{i} x_{i}-\sum_{\{i, j\} \notin E} c_{i j} y_{i j}+\sum_{\{i, j\} \in E} \lambda_{i j}^{1}\left(1-x_{i}-x_{j}\right) \\
 \tag{6}\\
+\sum_{\{i, j\} \notin E} \lambda_{i j}^{2}\left(1-x_{i}-x_{j}+y_{i j}\right)  \tag{7}\\
\text { s.t. }  \tag{8}\\
x_{i} \in\{0,1\} \quad i \in V \\
\\
y_{i j} \in\{0,1\} \quad\{i, j\} \notin E .
\end{gather*}
$$

where $\lambda^{1}, \lambda^{2} \geqslant 0$ denote the Lagrange multiplier vectors corresponding to constraints (2) and (3). Let the Lagrange multipliers in Equation (6) take the same values, we obtain a simpler problem as follows,

$$
\begin{gather*}
L R(\lambda)=\max _{x, y} \sum_{i \in V} w_{i} x_{i}-\sum_{\{i, j\} \notin E} c_{i j} y_{i j}+\sum_{\{i, j\} \in E} \lambda\left(1-x_{i}-x_{j}\right) \\
 \tag{9}\\
+\sum_{\{i, j\} \notin E} \lambda\left(1-x_{i}-x_{j}+y_{i j}\right) \\
\text { s.t. } \\
x_{i} \in\{0,1\} \quad i \in V \\
\\
y_{i j} \in\{0,1\} \quad\{i, j\} \notin E .
\end{gather*}
$$

Let $n$ be the number of vertices in the considered graph, $|E|$ be the number of permanent edges, and $\left|E^{\prime}\right|$ be the number of removable edges. Then we write $L R(\lambda)$ as follows:

$$
\begin{align*}
& L R(\lambda)= \max _{x, y} \sum_{i \in V} w_{i} x_{i}-\sum_{\{i, j\} \notin E} c_{i j} y_{i j}+\sum_{\{i, j\} \in E} \lambda\left(1-x_{i}-x_{j}\right) \\
&+\sum_{\{i, j\} \notin E} \lambda\left(1-x_{i}-x_{j}+y_{i j}\right) \\
&=\max _{x, y} \sum_{i \in V} w_{i} x_{i}+\sum_{\{i, j\} \notin E}\left(\lambda-c_{i j}\right) y_{i j}+\lambda\left[\sum_{\{i, j\} \in E}\left(1-x_{i}-x_{j}\right)\right. \\
&\left.+\sum_{\{i, j\} \notin E}\left(1-x_{i}-x_{j}\right)\right] \\
&=\max _{x, y} \sum_{i \in V} w_{i} x_{i}+\sum_{\{i, j\} \notin E}\left(\lambda-c_{i j}\right) y_{i j}+\lambda\left[|E|+\left|E^{\prime}\right|\right. \\
&\left.\quad-\sum_{\{i, j\} \in E}\left(x_{i}+x_{j}\right)-\sum_{\{i, j\} \notin E}\left(x_{i}+x_{j}\right)\right] \\
&=\max _{x, y} \sum_{i \in V} w_{i} x_{i}+\sum_{\{i, j\} \notin E}\left(\lambda-c_{i j}\right) y_{i j}+\lambda\left[|E|+\left|E^{\prime}\right|\right. \\
&\left.\quad-\sum_{i \in V} d_{i} x_{i}-\sum_{i \in V}\left(n-1-d_{i}\right) x_{i}\right] \\
&= \max _{x, y} \sum_{i \in V}\left[w_{i}-\lambda(n-1)\right] x_{i}+\sum_{\{i, j\} \notin E}\left(\lambda-c_{i j}\right) y_{i j}+\lambda\left({ }_{2}^{n}\right) \tag{10}
\end{align*}
$$

where $d_{i}$ denotes the degree of the vertex $i \in V$ in the graph considering only permanent edges, and $\binom{n}{2}$ equals the number of edges in the complete
graph with $n$ vertices, i.e., $\binom{n}{2}=\frac{n(n-1)}{2}$. With Equation (10), the restricted Lagrangian relaxation problem of Equation (9) can be written as,

$$
\begin{gather*}
L R(\lambda)=\max _{x, y} \sum_{i \in V}\left[w_{i}-\lambda(n-1)\right] x_{i}+\sum_{\{i, j\} \notin E}\left(\lambda-c_{i j}\right) y_{i j}+\lambda\binom{n}{2} \\
\text { s.t. } x_{i} \in\{0,1\} \quad i \in V  \tag{11}\\
\\
y_{i j} \in\{0,1\} \quad\{i, j\} \notin E .
\end{gather*}
$$

Obviously, the optimal solution to Equation (11) only depends on the signs of the coefficients of the binary decision variables $x_{i}$ and $y_{i j}$. To achieve the optimal solution, we only need to set the binary decision variables $x_{i}$ and $y_{i j}$ with non-negative coefficient to 1 while setting those with negative coefficient to 0 . Therefore, for each $\lambda>0, L R(\lambda)$ can be computed according to Equation (12),

$$
\begin{equation*}
L R(\lambda)=\sum_{i \in V^{+}}\left[w_{i}-\lambda(n-1)\right]+\sum_{\{i, j\} \in E^{+}}\left(\lambda-c_{i j}\right)+\lambda\binom{n}{2} \tag{12}
\end{equation*}
$$

where $V^{+} \subseteq V$ and $E^{+} \subseteq E$ respectively denote the set of vertices with non-negative coefficient and the set of removable edges with non-negative coefficient,

$$
\begin{align*}
V^{+} & =\left\{v \in V \mid w_{i} \geqslant \lambda(n-1)\right\}  \tag{13}\\
E^{+} & =\left\{(i, j) \notin E \mid c_{i j} \leqslant \lambda\right\} \tag{14}
\end{align*}
$$

Both $V^{+}$and $E^{+}$depend on their revenues (costs) and the Lagrangian multiplier $\lambda$. Then for a given value $\lambda>0, L R(\lambda)$ in Equation (12) provides an upper bound to the optimal value of GIS. To obtain an upper bound as tight as possible, we need to identify a value for $\lambda$ that minimizes $L R(\lambda)$ as much as possible.

In Equation (12), its left part $\sum_{i \in V^{+}}\left[w_{i}-\lambda(n-1)\right]$ decreases with $\lambda$ whereas its right part $\sum_{\{i, j\} \in E^{+}}\left(\lambda-c_{i j}\right)+\lambda\binom{n}{2}$ increases with $\lambda$, and it is difficult to determine the best value for $\lambda$ that minimizes Equation (12). Then we try to identify an appropriate value for $\lambda$ which could lead to as smaller value for $L R(\lambda)$ as possible. Let $w_{\text {max }}$ be the maximum revenue of the vertices in the considered graph, i.e., $w_{\max }=\max \left\{w_{v}: v \in V\right\}$. For $\lambda \geqslant \frac{w_{\max }}{n-1}, V^{+}$becomes empty and $\sum_{i \in V^{+}}\left[w_{i}-\lambda(n-1)\right]=0$, then $L R(\lambda)$ in Equation (12) increases for $\lambda \in\left(\frac{w_{\max }}{n-1},+\infty\right)$. As a result, we can restrict the optimization interval for $\lambda$ to $\left[0, \frac{w_{\max }}{n-1}\right]$. When $0 \leqslant \lambda \leqslant \frac{w_{\max }}{n-1}$, the monotonicity of $L R(\lambda)$ is not clear as it depends on both the revenues of the vertices and the cost of the edges in the considered graph. Then we test different values for $\lambda \in\left[0, \frac{w_{\max }}{n-1}\right]$, and experimental results indicate that $\lambda=\frac{w_{\max }}{n-1}$ is a good choice which can lead to
a smaller value for $L R(\lambda)$. With the analysis above, we can obtain an upper bound for the GIS defined by $L R(\lambda)$ with $\lambda=\frac{w_{\max }}{n-1}$, that is,

$$
\begin{equation*}
W^{*} \leq L R\left(\frac{w_{\max }}{n-1}\right)=\sum_{\{i, j\} \in E^{+}}\left(\frac{w_{\max }}{n-1}-c_{i j}\right)+\frac{n}{2} w_{\max } \tag{15}
\end{equation*}
$$

where $E^{+}=\left\{(i, j) \notin E \left\lvert\, c_{i j} \leq \frac{w_{\max }}{n-1}\right.\right\}$.
Then given the current independent set $I$ and its corresponding expending candidate list $P$, the following pruning strategy is employed in our $\mathrm{B} \& \mathrm{~B}$ algorithm. Precisely, let $G_{P}$ be the subgraph induced by $P$, and $U B\left(G_{P}\right)$ be the Lagrangian relaxation upper bound calculated by Equation (15) on $G_{P}$. In the case that $U B\left(G_{P}\right) \geq \sum_{i \in P} w_{i}, U B\left(G_{P}\right)$ is simply set to be $\sum_{i \in P} w_{i}$. For any independent set $I^{0}$ in $G$, let $W\left(I^{0}\right)=\sum_{i \in I^{0}} w_{i}-\sum_{i, j \in I^{0},\{i, j\} \in E^{\prime}} c_{i j}$ be the net benefit of $I^{0}$. Then given an arbitrary independent set $I^{\prime}$ in $G_{P}$, we have $W\left(I \cup I^{\prime}\right)=W(I)+W\left(I^{\prime}\right)-\sum_{i \in I, j \in I^{\prime},\{i, j\} \in E^{\prime}} c_{i j} \leq W(I)+W\left(I^{\prime}\right) \leq$ $W(I)+U B\left(G_{P}\right)$. Therefore, the search subtree rooted at $I$ and $P$ can be safely pruned if the following pruning condition is satisfied,

$$
\begin{equation*}
W(I)+U B\left(G_{P}\right) \leq W_{\max } \tag{16}
\end{equation*}
$$

where $W_{\max }$ is the maximum net benefit of the independent set found so far.

### 3.3 The branching strategy

At each branching step, a branching rule is applied to determine the next vertex $v$ to be selected from $P$ to append to the current independent $I$. A simple branching strategy is employed in our B\&B algorithm. Initially, vertices in the original graph $G$ are sorted in a descending order with respect to their revenues, and then copied back to $P$ according to that sorting order. Then at each level of recursion, the vertices in the candidate set $P$ are always kept in the same order as they initially appear in $P$, and the first vertex in $P$ is always selected with priority to be added to the current independent set $I$.

## 4 An adaptive local search for GIS

To solve larger instances for GIS, we propose an adaptive local search for GIS, which is also used in our proposed branch and bound algorithm to produce a tight initial lower bound. Our proposed adaptive local search (ALS) is based on the tabu search framework which has been successfully applied in a wide range of combinatorial optimization problems (Glover \& Laguna 1998). As shown in Algorithm 2, ALS starts with an initial solution $S$ (line 1 in Alg.
2) generated by the randomized procedure presented in Section 4.1. Then it repeats the main 'while' loop after initializing the best solution $S_{\text {best }}$ found so far with $S$ (line 2 in Alg. 2). For each iteration of the main loop, ALS jointly explores four neighborhoods and selects a best admissible neighboring solution from the neighborhood that is chosen in an adaptive manner (lines 5-6 in Alg. 2). Whenever an improved solution $S$ is found during the search, $S_{\text {best }}$ is updated with $S$ (lines 8-10 in Alg. 2). The ALS algorithm continues this process until the given stopping condition (typically a cutoff time limit) is verified.

```
Algorithm 2 The adaptive local search for GIS
Require: An initial solution \(S_{\text {initial }}\), time limit \(t_{\text {max }}\)
Ensure: The best solution found \(S_{\text {best }}\)
    \(S \leftarrow S_{\text {initial }} / *\) Apply a randomized procedure to generate an initial
    solution */
    \(S_{\text {best }} \leftarrow S_{\text {initial }}\)
    Iter \(\leftarrow 0\)
    while Time ()\(<t_{\max }\) do
        Construct neighborhoods \(N_{1}, N_{2}, N_{3}\) and \(N_{1} \cup N_{2} \cup N_{3}\) from \(S\)
        Choose a candidate solution \(S^{\prime}\) according to the neighborhood
    exploration rule as described in Section 4.2
        \(S \leftarrow S^{\prime}\)
        if \(f(S)>f\left(S_{\text {best }}\right)\) then
            \(S_{\text {best }} \leftarrow S\)
        end if
        Iter \(\leftarrow\) Iter +1
    end while
    return \(S_{\text {best }}\)
```

### 4.1 Randomized procedure for initial solutions

Our ALS procedure begins with an initial solution $I$ and then improves $I$ by maximizing its net benefit $W(I)$. The initial solution $I$ is constructed using the following randomized procedure. A seeding vertex $i$ is first randomly selected from $V$ and the current independent set $I$ is set to be composed of only this single vertex. Then at each step, among the candidate set of vertices $P=\{u: u \in V \backslash I,\{u, i\} \notin E, \forall i \in I\}$, (i.e., a vertex $u \in P$ is never connected to any vertex in $I$ by a permanent edge), a vertex $v$ is selected randomly and put in $I$. The above process is repeated until the candidate set $P$ becomes empty.

### 4.2 Neighborhood structures

The ALS procedure jointly explores three neighborhoods induced by three basic move operators. The definition of these three move operators are based on two vertex subsets: $P A$ and $O M$ relative to the current independent set $I$.
$P A$ consists of all vertices which are excluded from $I$ and connected to none of the vertices in $I$ by a permanent edge, i.e., $P A=\{v: v \in V \backslash I,\{v, i\} \notin$ $E, \forall i \in I\}$. We can append any vertex $v \in P A$ to $I$ such that the resulting solution is still a feasible independent set.
$O M$ is composed of all vertices which are excluded from $I$ and connected to only one vertex in $I$ by a permanent edge, i.e., $O M=\{v: v \in V \backslash I, \mid$ $N(v) \cap I \mid=1\}$ where $N(v)=\{u:\{v, u\} \in E\}$ denotes the set of vertices connected to $v$ by permanent edges. We can swap a vertex $u \in O M$ with the only vertex $v \in I$ connected to $u$ such that the resulting solution remains to be a feasible independent set.

Based on the subsets $P A$ and $O M$, the three move operators employed in our ALS procedure are defined as follows.
$-A D D(i)$ : This move operator is applied only when $P A$ is not empty and consists in appending a vertex $i \in P A$ to the current solution $I$. The neighborhood defined by the $A D D$ move operator is denoted by $N_{1}$. One key concept related to a move is the move gain, which measures how much the net benefit of the current solution $I$ is changed when a move is applied to $I$. For a fast calculation of the move gain, a $n$-dimensional $(n=|V|)$ vector $B$ then is used where $B_{i}=w_{i}-\sum_{\{u, i\} \in E^{\prime}, u \in I} c_{u i}$ denotes the potential contribution of a vertex $i$ to the net benefit of the current independent set. With the vector $B$, the move gain of appending a vertex $u \in P A$ can be fast computed by the following expression:

$$
\begin{equation*}
\Delta_{i}=B_{i} \tag{17}
\end{equation*}
$$

Obviously, the calculation of the move gain value for an add move can be achieved with a complexity of $O(1)$. After an $A D D(i)$ move is performed, the vector $B$ can be fast updated by the following expression:

$$
\begin{equation*}
B_{u}=B_{u}-c_{u i}, \forall\{u, i\} \in E^{\prime} \tag{18}
\end{equation*}
$$

Therefore, for each performed add move, the vector $B$ is updated in $O(n)$.
$-D R O P(i)$ : This move operator consists in dropping a vertex $i \in I$ from the current solution $I$. The neighborhood defined by the $D R O P$ move operator is denoted by $N_{2}$. With the vector $B$, the move gain value of dropping a vertex $i \in I$ (i.e., denoted by $\Delta_{i}$ ) can be quickly calculated using the following
equation:

$$
\begin{equation*}
\Delta_{i}=-B_{i} \tag{19}
\end{equation*}
$$

After performing a drop move denoted by $\operatorname{DROP}(i)$, the vector $B$ can be quickly updated in the following manner:

$$
\begin{equation*}
B_{u}=B_{u}+c_{u i}, \forall\{u, i\} \in E^{\prime} \tag{20}
\end{equation*}
$$

Therefore, the vector $B$ after a drop move is also updated in $O(n)$.
-SW AP $(i, j)$ : This move operator is applied only when the subset OM is not empty and consists in exchanging a vertex $i \in O M$ with the only vertex $j \in I$ which is connected to $i$ in $I$. The neighborhood defined by the SWAP move operator is denoted by $N_{3}$. With the vector $B$, the move gain of a swap move, denoted by $\Delta_{i j}$, can be fast calculated as follows.

$$
\begin{equation*}
\Delta_{i j}=B_{i}-B_{j} \tag{21}
\end{equation*}
$$

It is noted that a swap move $S W A P(i, j)$ can be decomposed into a drop move $\operatorname{DROP}(j)$ followed by an add move $A D D(i)$. Thus in order to update the vector $B$ after a swap move $S W A P(i, j)$, we could first apply Equation (20) to update the change induced by $\operatorname{DROP}(j)$, then use Equation (18) to update the change induced by $A D D(i)$. It is clear that the update of vector $B$ after a swap move can also be implemented in $O(n)$.

When several neighborhoods are available, the method to combine these neighborhoods so as to enhance the search ability of the algorithm becomes essential. There are several methods to effectively explore the neighborhoods in the literature, such as neighborhood union, probabilistic neighborhood union, and token-ring search (Hao 2012). For instance in Wu et al. (2012), the union of the basic neighborhoods induced by the $A D D, S W A P$, and $D R O P$ moves is explored for solving the maximum weight clique problem. The motivation for combining multiple neighborhoods is to allow the algorithm to examine candidate solutions with different structures and characteristics, increasing its chance to discover high-quality optima. After testing different methods for combining the basic neighborhoods induced by the $A D D, S W A P$, and $D R O P$ moves, the following adaptive rule is adopted in our ALS procedure.

The ALS algorithm jointly considers four neighborhoods denoted by $N_{1}, N_{2}$, $N_{3}$ and $N_{1} \cup N_{2} \cup N_{3}$ (i.e., the union of $N_{1}, N_{2}$ and $N_{3}$ ), and selects one of these four neighborhoods to explore in a probabilistic way at each iteration. Specifically, we employ four counters $\sigma_{1}, \sigma_{2}, \sigma_{3}$, and $\sigma_{4}$ to respectively record the number of times each neighborhood improves the recorded best solution. At the start of the search, we set the probability of choosing the four neighborhoods to be $\frac{\sigma_{i}}{\sum_{j=1}^{4_{j}} \sigma_{j}}$ with $\sigma_{i}=1(i=1,2,3,4)$. At each iteration of the local search, one of the four neighborhoods is selected according to the
given probability, and the best admissible solution is selected from this chosen neighborhood to replace the current solution. Ties are broken randomly when multiple moves have the same gain. During the search process, each time the selected neighborhood produces an updated best solution, its probability is updated by increasing the corresponding $\sigma$ value by 1 . In such a manner, the chance to apply the neighborhood generating high-quality solutions is increased. We mention that compared with the neighborhood union strategy proposed by Wu et al. (2012), which only explores the union of the three neighborhoods, and ensures an intensified and aggressive examination of the search space, our adaptive selection strategy offers more search diversification, and favors a better search balance between intensification and diversification.

Finally, a simple tabu mechanism is adopted to prevent the search from shortterm cycles, which forbids a vertex moved by the $A D D, S W A P$, and $D R O P$ operators to be moved again for the next $t l$ iterations, where $t l$ is a parameter called tabu tenure (Glover \& Laguna 1998).

## 5 Computational experiments

This section is dedicated to an extensive evaluation of the proposed exact and heuristic approaches. For this purpose, we present experimental results achieved by our exact and heuristic approaches on a large set of benchmark instances and compare them with other state-of-the-art exact and heuristic methods for the GIS proposed in the literature.

### 5.1 Test instances and parameter settings

The proposed LA-B\&B and ALS approaches are both tested on a set of 216 benchmark instances which were first introduced by Colombi et al. (2017). The generation of these instances is based on 12 DIMACS graphs (Johnson \& Trick 1996) with 125 to 400 vertices and 6963 to 71820 edges. The DIMACS graph set includes randomly generated graphs, graphs where the optimal solution has been hidden by incorporating low-degree vertices, as well as graphs constructed from various applications, such as coding theory, fault diagnosis problems, Keller's conjecture on tilings using hypercubes, and the Steiner triple problem. Each of these 12 graphs is associated with three different sets of removable edges and six different values for the revenue and cost, leading thus to a total of 216 instances 1 . In these benchmark instances, each edge of the graph is
$\overline{1 \text { The benchmark instances are available at https://or- }}$ dii.unibs.it/index.php?page=gisp.
randomly marked as a removable edge with a probability $p_{r}$, such that three classes of instances were produced by considering $p_{r}=0.25,0.50$ and 0.75 . For each instance class generated with a fixed $p_{r}$ value, the following two sets of instances were generated by imposing different values for the revenue and cost.

- SET1: for each vertex $i$, its revenue value is set to an integer randomly taken in $\{1, \ldots, 100\}$, while for each removable edge $\{i, j\} \in E^{\prime}$, its associated cost is set to three different values $c_{i j}=\left[\frac{1}{100}\left(w_{i}+w_{j}\right)\right],\left[\frac{1}{50}\left(w_{i}+w_{j}\right)\right]$, and $\left[\frac{1}{25}\left(w_{i}+w_{j}\right)\right]$, where [.] denotes the closest rounded integer.
- SET2: for each vertex $i$, its revenue value is set to three different values $w_{i}=$ 100,50 , and 25 , while for each removable edge $\{i, j\} \in E^{\prime}$, its associated cost is set to $c_{i j}=1$.

The instances generated with the three different $p_{r}$ values in both sets are marked with A, B, and C in their names, respectively.

In addition to these 216 standard instances, and to further evaluate the performance of our ALS approach on larger instances, we randomly selected 15 graphs from the OpenStreetMar ${ }^{2}$ files of North America and 15 graphs from the PACE 2019 Challenge (Dzulfikar et al. 2019). The OpenStreetMap graphs are vertex-weighted, generated by associating map labels with vertices and assigning each vertex a weight based on the importance of the corresponding map label. The graphs from the PACE 2019 Challenge are from various domains and have been gathered from eight different sources ${ }^{3}$ These 30 selected graphs have a larger number of vertices, ranging from 786 to 17,903 , and a greater number of edges, ranging from 1,948 to 604,867 . These instances have been previously used in the literature to test the minimum vertex cover problem and the maximum weight independent set problem (Cai et al. 2018; Lamm et al. 2019). Since the density of the graphs from the PACE 2019 Challenge and OpenStreetMap is very low (generally below 0.1), we additionally include all the 17 graphs with at least 700 (up to 4000) vertices and 6480 to 3997732 edges from the DIMACS benchmark, and use the inverted versions of these original graphs by transforming them into their complementary graphs. In total, we obtain 47 diverse large GIS instances. In these 47 large graphs, each edge of the graph is randomly marked as a removable edge with a random probability $p_{r}=0.25,0.50$ and 0.75 , and the cost of each removable edge is set in the same way as for the SET1-C instances. The revenue value of each vertex in the graphs from the DIMACS benchmark and PACE 2019 Challenge is set in the same way as for the SET1-C instances, while for the OpenStreetMap graphs, we retain the original vertex weights as the vertex revenues, given that these graphs are already vertex-weighted. As

[^1]a result, these graphs produce a total of 47 instances for the GIS problem ${ }^{4}$.
We set the parameter required by our ALS algorithm as follows: the tabu tenure $t l=7$. The setting of this parameter is tuned using the general IRACE automatic parameter configuration tool (López-Ibáñez et al. 2016). For this parameter tuning task, we used a different set of 20 instances with 100 to 400 vertices 5 , which are randomly generated as follows. Each pair of vertices is randomly marked as a permanent edge with a random probability $p_{1}$ from the range $[0.1,0.9]$. For each pair of vertices not connected by a permanent edge, it is randomly marked as a removable edge with a random probability $p_{2}$ from the range $[0.3,0.7]$. The revenue value of each vertex is set to a random integer value from $[10,100]$, while for each removable edge, its cost is set to a random integer value from $[1,5]$.

### 5.2 Experimental protocol and reference algorithms

To show the effectiveness of our proposed LA-B\&B and ALS algorithms, we compare them respectively with the currently best-performing exact and heuristic approaches for the GIS. As shown in the most recent study (Hosseinian \& Butenko 2019; Nogueira et al. 2021), the following two reference algorithms are among the best exact and heuristic methods for the GIS, and thus constitute the reference approaches to evaluate the performance of our LA-B\&B and ALS algorithms.

- CB\&B: A combinatorial B\&B (CB\&B) method (Hosseinian \& Butenko 2019), which also relies on the branch and bound framework similar to our LA-B\&B algorithm, but uses different bounding and branching strategies. Specifically, CB\&B takes advantage of a nonlinear formulation of the GIS problem and employs a spherical relaxation of a quadratic function over a hypersphere in its bounding subroutine. Additionally, CB\&B employs a branching strategy where the vertices in the graph $G=(V, E)$ ( $E$ denotes the set of permanent edges) are sorted in a descending order of their degrees, and the vertices are selected in that order at each branching step.
- ILS-VND: A variable neighborhood descent based iterated local search heuristic approach (Nogueira et al. 2021), which relies on two neighborhoods, one involving the addition of a single vertex to the solution, and the other involving the addition of two vertices. These two neighborhoods are explored using a variable neighborhood descent procedure. ILS-VND differs

[^2]from our ALS algorithm mainly in its neighborhoods and the manner in which it explores the neighborhoods.

Moreover, the above reference approaches are tested very recently by Nogueira et al. (2021) under the same platform (an Intel i7 processor with 3.6 GHz and 16 GB of memory). The source codes of CB\&B and ILS-VND were made available by the authors. To make the comparison as fair as possible, we run the source codes of these reference algorithms on our computing platform under the same time limit as adopted by Hosseinian \& Butenko (2019) and Nogueira et al. (2021), which is set to be 3 hours for CB\&B and LA-B\&B, and 30 seconds for ILS-VND and ALS on the SET1 and SET2 instances. In addition, for the 47 larger instances generated in this work, we set the time limit to be 5 minutes.

Our LA-B\&B and ALS approaches ${ }^{6}$ are programmed in Java and compiled on an Intel i5 processor with 2.8 GHz CPU and 16G RAM. Our platform requires respectively $0.31,1.93$ and 7.35 CPU seconds for the graphs r300.5, r400.5 and r500.5 when running the DIMACS MC Machine Benchmark program (available at http://archive.dimacs.rutgers.edu/pub/dsj/clique/).

### 5.3 Computational results of $L A-B \xi B$

We assess the performance of the LA-B\&B algorithm by comparing it with the reference algorithm CB\&B introduced in Section 5.2. In this comparison, the reference CB\&B algorithm did not include a procedure to generate a tight initial lower bound for its pruning subroutine. Therefore, our LA-B\&B algorithm excludes the ALS procedure from its branch and bound framework to ensure a fair comparison with the reference method. Table 2 summarizes the comparative results between LA-B\&B and CB\&B on the whole set of the 216 instances while Tables 5-7 in the Appendix present the detailed results for each instance. Columns 1-2 in Table 2 respectively give the name of each instance set and the number of instances in each set. Columns 3-8 summarize the results obtained by the two compared algorithms on each instance set, including the number of instances solved to optimality, the required computation time averaged on the instances solved to optimality, and the number of better results in terms of lower bounds on instances where both algorithms fail to obtain the optimal solution. Finally, the summarized results for each column are presented in the last row of the table.

When comparing $C B \& B$ with our LA-B\&B algorithm, one observes that LA$\mathrm{B} \& \mathrm{~B}$ is able to solve 143 instances ( $66 \%$ ) to optimality within the given

[^3]Table 2
Summary of comparative results on the 216 standard GIS benchmark instances between LA-B\&B and CB\&B

| Set | Total | LA-B\&B |  |  | CB\&B |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: | :---: |
|  |  | \#Optimality | Avg. time(s) | \#Better lower bound | \#Optimality | Avg. time(s) | \#Better lower bound |
| $p_{r}=0.25$ |  |  |  |  |  |  |  |
| SET1 | 36 | 33 | 54.68 | 3 | 33 | 586.50 | 0 |
| SET2 | 36 | 33 | 843.52 | 3 | 33 | 979.79 | 0 |
| $p_{r}=0.5$ |  |  |  |  |  |  |  |
| SET1 | 36 | 30 | 64.60 | 6 | 26 | 4092.37 | 0 |
| SET2 | 36 | 30 | 207.29 | 3 | 20 | 5314.38 | 3 |
| $p_{r}=0.75$ |  |  |  |  |  |  |  |
| SET1 | 36 | 10 | 2508.35 | 26 | 3 | 7698.81 | 0 |
| SET2 | 36 | 7 | 3503.61 | 28 | 3 | 6515.30 | 0 |
| Summary | 216 | 143 | 1197.01 | 69 | 118 | 4197.86 | 3 |

time limit of 3 hours, while CB\&B can only solve 118 instances (54\%) to optimality. For the 73 instances where both exact algorithms fail to reach the optimal solutions within the given time limit, our LA-B\&B algorithm is able to achieve better lower bounds on 69 instances but worse lower bounds on 3 instances. In terms of the computational efficiency, LA-B\&B requires a significantly shorter average time on the instances solved to optimality. Especially, as shown by the detailed results in Tables 5.7, our LA-B\&B algorithm is 10 times faster than the CB\&B method to solve 112 out of the 118 instances solved by both algorithms. The advantage of our LA-B\&B algorithm in terms of the computational efficiency becomes even more evident when the removable-edge density of the graphs decreases. For 96 out of the 112 instances with the removable-edge density $\rho_{2} \leq 0.5$, our LA-B\&B algorithm is 100 times faster than the CB\&B method to reach the optimal solution. For 12 out of the 67 instances with the removable-edge density $\rho_{2} \leq 0.25$, our LA-B\&B algorithm is even 1000 times faster than the CB\&B method. These observations demonstrate that our proposed LA-B\&B algorithm is highly efficient for the GIS compared to the currently best-performing exact approach.

By incorporating the tight initial lower bound produced by the adaptive local search procedure ALS, the performance of the LA-B\&B algorithm can be further improved. Columns 9-10 in Tables 5-7 provide the detailed results of LA-B\&B with the initial lower bound (denoted by LA-B\&B+ALS) on the 216 instances. As shown by columns $9-10$ in Tables 55.7. LA-B\&B+ALS is able to solve one more instance to optimality within the given time limit. In terms of the average computation time for the instances solved to optimality by both algorithms, LA-B\&B+ALS requires less time than LA-B\&B. Finally, for these instances where both algorithms fail to attain the optimal solution, LA$\mathrm{B} \& \mathrm{~B}+\mathrm{ALS}$ is able to produce better lower bounds on much more instances than LA-B\&B. These comparative results clearly demonstrate the improved performance of LA-B\&B when incorporating the tight initial lower bound produced by ALS.

### 5.4 Computational results of $A L S$

To demonstrate the effectiveness of our heuristic approach ALS in terms of producing highly competitive results (lower bound), we compare it with the currently best-performing heuristic approach ILS-VND. Given the stochastic nature of the two compared algorithms, each instance is solved 10 times independently with different random seeds by each algorithm under the same experimental protocol as described in Section 5.2. Table 3 summarizes the comparative results between ALS and ILS-VND on the whole set of the 216 instances while Tables 810 in the Appendix present the detailed results per instance. Columns 1-2 in Table 3 respectively show the name of each instance set and the number of instances in each set. The remaining columns give the number of instances where our ALS algorithm achieves better (\#Wins), equal (\#Ties) or worse (\#Losses) results compared to ILS-VNS in terms of the best objective value $\left(f_{\text {best }}\right)$, the average objective value ( $f_{\text {avg }}$ ), and the average running time in seconds (time $(s)$ ) to reach the best result across the 10 independent runs. We also present the average percentage improvement (Avg. Imp) of ALS over ILS-VND in terms of the best or average objective value across the 36 instances in each set. For each instance set, the average percentage improvement of the best and the average objective value are computed as $\frac{\sum_{i=1}^{36}\left(f_{A L S}^{i}-f_{I L S-V N D}^{i}\right) / f_{A L S}^{i}}{36} \times 100$, where $f_{A L S}^{i}\left(f_{I L S-V N D}^{i}\right)$ is the best or the average objective value obtained by the given algorithm on the $i$ th instance in the set. The summarized results for each column are presented in the last row of Table 3 .

From Table 3, one can observe in terms of the best objective value $f_{\text {best }}$, our ALS is able to obtain respectively 1 better, 215 equal, and 0 worse results compared to ILS-VND, while in terms of the average objective value $f_{\text {avg }}$, our ALS is capable of achieving respectively 16 better, 200 equal, and 0 worse results. In terms of the computation time, our ALS algorithm requires a shorter time than ILS-VND to find equal or better solutions for 215 out of the 216
instances. Furthermore, as shown by the detailed results in Tables 8 - 10 in Appendix, our ALS approach is able to improve the previous best known result (new lower bound) for one instance (gen400_p0.9_75_B_75), and it reaches its best solutions with a success ratio of $100 \%$ for all the 216 tested instances, while this is done by ILS-VND only for 200 cases within the given time limit, further confirming the robustness of the proposed ALS. We can conclude that ALS is highly efficient for the GIS compared to the currently best-performing heuristic approach proposed in the literature.

### 5.5 Computational results of ALS on large instances

To further evaluate the performance of the proposed ALS algorithm, this section experimentally compares ALS with the reference algorithm ILS-VND on the 47 large instances. The comparison is carried out under the same experimental protocol described in Section 5.2. Table 4 summarizes the comparative results. The first six columns in Table 4 respectively indicate the instance name (Instance), the number of vertices $(|V|)$, the number of permanent edges $(|E|)$, the number of removable edges $\left(\left|E^{\prime}\right|\right)$, the permanentedge density $\rho_{1}$ (computed as $\frac{2|E|}{|V|(|V|-1)}$ ), and the removable-edge density $\rho_{2}$ (computed as $\left.\frac{2\left|E^{\prime}\right|}{|V|(|V|-1)}\right)$. Columns $7-14$ report the results obtained by the two compared heuristic approaches, including the best solution $\left(f_{b e s t}\right)$, the average result $\left(f_{\text {avg }}\right)$, the success rate (success) to achieve the best result, and the average running time (time (s)) in seconds needed to reach the best result. For each instance where ALS and ILS-VND reach different best or average values, we also indicate in parentheses the percentage improvement of ALS over ILS-VND, which is calculated as $\left(f_{A L S}-f_{I L S-V N D}\right) / f_{A L S} \times 100$, where $f_{A L S}$ and $f_{I L S-V N D}$ respectively represent the best or average result obtained by the two compared methods. Additionally, in the last four rows, we present the summarized results between the two compared algorithms, including the number of instances where each algorithm performed better in terms of the best and average results, the average running time to reach the best result, and the $p$-value from the Wilcoxon signed-rank test.

Table 4 shows that our ALS algorithm achieves highly competitive results compared to ILS-VND. In terms of the best objective value, ALS is able to find a better, equal and worse result on $22,21,4$ instances respectively compared to ILS-VND, while in terms of the average objective value, ALS is able to find a better, equal and worse result on 30,11, 6 instances respectively. Regarding the computation time required by both algorithms to reach their best objective value, ALS is faster than ILS-VND on 16 out of the 21 instances where both algorithms reach the same best result. Finally, the $p$-values $(<0.05)$ of the Wilcoxon signed-rank test indicates a significant difference between ALS and ILS-VND in terms of the best result, average result and computation time.
Table 4: Summary of comparative results between ALS and ILS-VND on the 47 large PACE, OpenStreetMap and DIMACS instances

## 6 Analysis

In this section, we focus our attention on the analysis of the main components of our proposed LA-B\&B algorithm in order to show their important roles to the performance of LA-B\&B.

### 6.1 Impact of the Lagrange multiplier in the upper bound

In Section 3.2, we derived an upper bound on the Lagrange multiplier $\lambda$. Our analysis revealed that the optimal value for $\lambda$ falls within the interval $[0, \alpha]$, where $\alpha=\frac{w_{\max }}{n-1}$. To determine a suitable value for $\lambda$ in the interval $[0, \alpha]$, we evaluated the LA-B\&B algorithm using four different values for the Lagrange multiplier. These four values were chosen as $\lambda_{i}=0.25 \times i \times \alpha(i=$ $1,2,3,4)$. To conduct this comparison, we executed the LA-B\&B algorithm with the four chosen values for $\lambda$. We then compared the computational time required by the LA-B\&B algorithm with the four chosen $\lambda$ values to reach the optimal solution. We excluded the initial lower bound and followed the same experimental protocol described in Section 5.2. The evaluation was performed on 36 instances which were randomly selected from the 216 instances.

Fig. 2(a) summarizes the normalized running time required by the LA-B\&B algorithm with the four chosen values for $\lambda$. The horizontal axis in Fig. 2(a) indicates the names of the instances, while the vertical axis indicates the normalized running time required by the LA-B\&B with the four chosen values for $\lambda$, respectively. Due to significant variations in running time across different instances, we normalize the running time required by the LA-B\&B with the chosen $\lambda$ values using the running time required by LA-B\&B with $\lambda_{4}$ as a baseline. Specifically, for a given instance, the running time required by LA$\mathrm{B} \& \mathrm{~B}$ with $\lambda_{i}(i=1,2,3,4)$ is normalized by $\frac{t_{i}}{t_{4}}$, where $t_{i}$ is the runtime required by LA-B\&B with $\lambda_{i}$ to reach the optimal solution on that instance. If the instance can not be solved to optimality with the given time of 10800 seconds by LA-B\&B with $\lambda_{i}, t_{i}$ is set to be 10800 seconds. As shown by Fig. 2(a), LA-B\&B with $\lambda_{4}$ shows an overall best performance among the four compared variants. For the 29 instances where LA-B\&B with all $\lambda_{i}$ can reach the optimal solution, LA-B\&B with $\lambda_{4}$ is able to reach the optimal solution within the shortest running time on 22 cases. Additionally, Fig. 2(a) reveals that the running time required by the four variants typically falls within the range of $\left[0.8 t_{4}, 1.4 t_{4}\right]$ across most of the 36 instances, indicating the differences in running time between the four compared variants are relatively small.

To further investigate the influence of Lagrange multipliers on the tightness of the bound, we present in Fig. 2(b) the ratio of the best upper bound achieved
by employing the Lagrangian relaxation method with the four selected values for the Lagrange multiplier. Specifically, for a given instance, we calculate the Lagrangian relaxation upper bound $U B\left(G_{P}\right)$ at each bounding step using the four chosen values for the Lagrange multiplier, where $G_{P}$ represents the subgraph induced by $P$. We then track the number of times each chosen value for the Lagrange multiplier produces the best Lagrangian relaxation upper bound during the LA-B\&B search, denoted as $n_{1}, n_{2}, n_{3}$, and $n_{4}$ respectively. Afterward, we compute the ratio of the best upper bound achieved by each chosen value $\lambda_{i}$ as $\frac{n_{i}}{\sum_{j=1}^{4_{i} n_{j}}} \times 100$. From Fig. 2(b), we can observe that $\lambda_{i}=\alpha$ shows a slightly overall better performance by achieving the largest ratio on 18 out of the 36 instances. Especially, for several instances where the revenues of the vertices are very evenly distributed, $\lambda_{4}=\alpha$ is able to produce the best Lagrangian relaxation upper bound with a ratio of nearly $100 \%$. Intuitively, when the revenues of the vertices are evenly distributed, the revenues of all vertices are close to $w_{\max }$. This results in the first part of Equation 12 (i.e., $\left.\sum_{i \in V^{+}}\left[w_{i}-\lambda(n-1)\right]\right)$, used for calculating the Lagrangian relaxation upper bound, approaching 0 when $\lambda$ is set to $\alpha=\frac{w_{\max }}{n-1}$. This can potentially lead to a significantly better upper bound. However, on instances where the revenues of the vertices exhibit a wider range of variation, other values for $\lambda$ enable the LA-B\&B algorithm to perform much better compared to $\lambda=\alpha$. We conclude that no single $\lambda$ dominates the others on all these 36 instances, and the performance of the Lagrangian relaxation method with each Lagrange multiplier varies with the specific instance, making it difficult to determine the best value for $\lambda$.

### 6.2 Effectiveness of the Lagrangian relaxation upper bound

As shown in Section 3.2, the LA-B\&B algorithm employs two upper bounding strategies for its pruning subroutine. The first strategy is the Lagrangian relaxation upper bounding strategy (LUB), while the second strategy is a simple upper bounding strategy (SUB) that relies on the revenues of the vertices in $P$ (i.e., $\sum_{i \in P} w_{i}$ ) to compute an upper bound on the net benefit of the subgraph $G_{P}$. In this section, we analyze the frequency that the two bounding strategies are used for pruning to demonstrate their contributions to the LA-B\&B algorithm. The evaluation was performed on the same 36 instances used in Section 6.1.

Fig. 3 summarizes the frequency that the two bounding strategies are used for pruning on the 36 instances. The horizontal axis in Fig. 3 indicates the the names of the instances, while the vertical axis represents the frequency of application for the two strategies, which is defined as $\frac{n_{1}}{n_{1}+n_{2}}$ (or $\frac{n_{2}}{n_{1}+n_{2}}$ ) where $n_{1}$ and $n_{2}$ respectively denotes the number of times that LUB and SUB are

(a) The normalized running time required by the LA-B\&B algorithm using four different values for the Lagrange multiplier

(b) The ratio of the best upper bound achieved by employing the Lagrangian relaxation method with the four selected values for the Lagrange multiplier

Fig. 2. Comparisons of LA-B\&B algorithms with four different values of the Lagrange multiplier.
used for bounding during the search.
From Fig. 3, we can observe that both bounding strategies positively contribute to the performance of the LA-B\&B algorithm. However, LUB is generally applied with a higher frequency on many more instances. Especially, for several instances where the revenues of the vertices are very evenly distributed, LUB is applied with a frequency of $100 \%$, indicating that LUB can always produce better upper bound than SUB throughout the search process on these instances. As discussed in Section 6.1, when the revenues of the vertices are evenly distributed, the revenues of all vertices are very close to $w_{\max }$, allowing the LUB produce very tight upper bound on these instance. Further, LUB is more effective than SUB on instances with higher cost of the removable edges, since on these instances, SUB does not take the cost of
the removable edges into account. On the other hand, SUB works better than LUB on instances where the revenues of the vertices exhibit a wider range of variation, since on these instances, LUB considers the revenues of all vertices to be $w_{\max }$ (the maximum revenue) when bounding, leading to a less tighter bound on the revenues of all vertices. The above observation further confirms that LUB plays an important role to the performance of LA-B\&B.

Fig. 3. The frequency of LUB and SUB used for bounding

### 6.3 Impact of the branching strategy

As shown in Section 3.3 , the LA-B\&B algorithm employs a branching strategy where the vertices in the candidate list $P$ are sorted in decreasing order with respect to their revenue, and the vertices in $P$ are selected in that order. To verify the effectiveness of this branching strategy, we compare it with two other branching strategies widely used in the context of solving the independent set and clique problems. The first branching strategy selects the vertices in $P$ in an ascending order with respect to their revenue, while the second branching strategy selects the vertices in $P$ in an descending order with respective to the degree of the vertices, where the degree of a vertex $i$ in $P$ is defined by the number of permanent edges connected to $i$ in $P$. By replacing our adopted branching strategy with these two branching strategies, we obtain two LA-B\&B variants, which are respectively denoted by Ascend-B\&B and Degree-B\&B. To make a fair comparison, we run all three approaches without a initial lower bound under the same experimental protocol as described in Section 5.2 on the same 36 instances which are used in Section 6.1.

Fig. 4(a) and 4(b) illustrate the comparative performance of LA-B\&B, Ascend$\mathrm{B} \& \mathrm{~B}$, and Degree- $\mathrm{B} \& \mathrm{~B}$ on 36 instances. In Fig. 4(a), the horizontal axis represents the names of the instances, while the vertical axis indicates the percentage gap of the solution obtained by each method compared to the best

Fig. 4. Comparisons of LA-B\&B with its two variants.
solution achieved with all three compared methods. For each instance, the percentage gaps of the results are calculated as $\left(f-f_{b}\right) / f_{b} \times 100$, where $f$ represents the result obtained by each respective method, and $f_{b}$ represents the best solution achieved with all three methods. In Fig. 4(a), we present the normalized running time required by each compared algorithm using the running time required by LA-B\&B as a baseline.

From Fig. 4(a), it can be observed that within the given time limit, LA-B\&B achieves the best results for 35 instances, compared to 32 and 31 for Ascend-B\&B and Degree-B\&B, respectively. Moreover, in terms of computational time, Fig. 4(b) discloses that LA-B\&B is able to reach the optimal solution in a shorter average computational time compared to Ascend$\mathrm{B} \& \mathrm{~B}$ and Degree-B\&B. Overall, the $p$-values from the Wilcoxon signed-rank test demonstrate statistically significant difference between both LA-B\&B and
the two compared methods in terms of solution quality (4.31E-02 for LAB\&B vs Ascend-B\&B and 4.64E-02 for LA-B\&B vs Degree-B\&B). In terms of computational time, there is a statistically significant difference between LA-B\&B and Ascend-B\&B (2.45E-02 for LA-B\&B vs Ascend-B\&B), while no statistically significant difference is observed between LA-B\&B and DegreeB\&B (6.13E-02 for LA-B\&B vs Degree-B\&B).

### 6.4 Effectiveness of the adaptive neighborhood exploration strategy

When multiple neighborhoods are available, a crucial issue arises regarding how to effectively combine these neighborhoods to explore the search space efficiently. In our work, we proposed an adaptive neighborhood exploration strategy that dynamically selects the most promising neighborhood capable of generating high-quality solutions. To demonstrate the effectiveness of our proposed adaptive neighborhood exploration strategy, we compared it with a widely used method from the literature called the neighborhood union method, which jointly considers all neighborhoods and selects the best non-tabu neighboring solution from all considered neighborhoods. The neighborhood union method allows for an aggressive exploration of the search space, and has been proven to be effective in the context of local search for the maximum weight clique problem (Wu et al. 2012).

By keeping other ingredients unchanged, we conducted experiments on both strategies within our local search method under the same experimental protocol described in Section 5.2 on the 47 large instances. We refer to the variant using the neighborhood union strategy as ULS. In Fig. 5, the horizontal axis represents the serial number of the instances, while the vertical axis indicates the percentage gap of the solution obtained by each method compared to the best solution achieved by both methods. For each instance, the percentage gaps of the best and average results are calculated as $\left|f-f_{b}\right| / f_{b} \times 100$, where $f$ represents the best or average result obtained by the respective method, and $f_{b}$ represents the best solution achieved by both methods. From Fig. 5, we can observe that in terms of best results, our ALS algorithm achieves better, equal, and worse results respectively for 17, 21 and 9 instances. In terms of average results, ALS achieves better, equal, and worse results for $14,18,15$ instances. Overall, ALS shows a slightly better stability in achieving high quality solutions compared to ULS and also shows superiority in finding improved solutions, validating the effectiveness of our adaptive neighborhood exploration strategy for exploring the solution space. These findings highlight the potential of ALS in enhancing the performance of local searches.

Fig. 5. Comparisons of ALS with its variant ULS.

## 7 Conclusion

In this work, we studied the generalized independent set problem, which is an important generalization of the classical maximum independent set problem with various practical applications. To effectively solve the problem, we proposed highly effective exact and heuristic solution approaches. The exact method derives a new upper bound for the problem using a Lagrangian relaxation method, and a tight lower bound employing our proposed adaptive local search heuristic. By incorporating these lower and upper bound techniques into the general $\mathrm{B} \& \mathrm{~B}$ framework, we obtained an effective exact method for this challenging problem.

We assessed the performance of the proposed methods on a set of 216 benchmark instances in the literature and compared our results with those from the currently best-performing exact and heuristic approaches. The
comparative studies showed that our algorithms are highly competitive with the best reference algorithms. In particular, our exact algorithm was able to solve 26 more instances to optimality for the first time. We also carried out additional experiments to confirm the effectiveness of the proposed heuristic approach ALS on 47 new generated large instances, which is shown to be competitive with the currently best heuristic approach for generating highquality lower bounds for our studied problem.

## Acknowledgments

We are grateful to the anonymous referees for their valuable suggestions and comments, which helped us to improve the paper significantly. We would like to thank the authors of Hosseinian \& Butenko (2019) and Nogueira et al. (2021) for sharing the source codes of their algorithms. This work was partially supported by the National Natural Science Foundation Program of China (Grant No. 72122006).

## Appendix: Detailed computational results

Detailed comparative results between our exact LA-B\&B algorithm and the reference exact algorithm $C B \& B$ on the whole set of the 216 benchmark instances are provided in Tables 5-7. The first six columns in Tables 5•-7 respectively indicate the instance name (Instance), the number of vertices $(|V|)$, the number of permanent edges $(|E|)$, the number of removable edges $\left(\left|E^{\prime}\right|\right)$, the permanent-edge density $\rho_{1}$ (computed as $\frac{2||E|}{|V||V|-1)}$ ), and the removable-edge density $\rho_{2}$ (computed as $\frac{2\left|E^{\prime}\right|}{|V|(|V|-1)}$ ). Columns 7-10 present the results obtained by the two compared exact approaches under a time limit of 3 hours, including the best solution $f_{\text {best }}$ achieved by the algorithms (marked with an asterisk ' $*$ ' if the instance is solved to optimality by the corresponding algorithm), and the time required by the algorithm to solve the instance to optimality (denoted by 10800 seconds if the algorithm fails to attain the optimal solutions within the given time limit).

Detailed comparative results between the proposed heuristic algorithm ALS and the reference heuristic algorithm ILS-VND are presented in Tables 8.10 . Column 2 reports the previously best-known results reported in the literature (marked with an asterisk ' $*$ ' if the optimal solution for the instance is known). Columns 3-8 report for each algorithm the best result $\left(f_{\text {best }}\right)$, the average result $\left(f_{\text {avg }}\right)$, the success rate (success) to achieve the best result, and the average running time $(\operatorname{time}(s))$ in seconds to reach the best result across the 10 independent runs.

The best results found by the proposed algorithm ALS and the reference algorithm ILS-VND are marked in bold text.
